Discovery of VHE $\gamma$-ray emission and multi-wavelength observations of the BL Lacertae object 1RXS J101015.9−311909

ABSTRACT

1RXS J101015.9−311909 is a galaxy located at a redshift of $z = 0.14$ hosting an active nucleus (called AGN) belonging to the class of bright BL Lac objects. Observations at high (HE, $E > 100$ MeV) and very high (VHE, $E > 100$ GeV) energies provide insights into the origin of such sources and the radiation processes at work. We report on results from VHE observations performed between 2006 and 2010 with the H.E.S.S. instrument, an array of four imaging atmospheric Cherenkov telescopes. H.E.S.S. data have been available in electronic form at the CDS via anonymous ftp to cdsarc.u-strasbg.fr (130.79.128.5) or via http://cdsarc.u-strasbg.fr/viz-bin/qcat?J/A+A/542/A94

1. Introduction

BL Lac objects are characterised by rapid variability in all energy ranges, and often display jets with apparent superluminal motions. Their extreme properties are thought to be related to the

Key words. gamma rays: galaxies – galaxies: active – BL Lacertae objects: individual: 1RXS J101015.9−311909

* The data points from the light curves and the spectra are available in electronic form at the CDS via anonymous ftp to cdsarc.u-strasbg.fr (130.79.128.5) or via http://cdsarc.u-strasbg.fr/viz-bin/qcat?J/A+A/542/A94

** Supported by Erasmus Mundus, External Cooperation Window.
relativistic bulk motion of the emitting region at small angles to the line of sight of the observer. In addition, these objects show highly polarized emission and no or only weak emission lines. The observed broadband spectral energy distribution (SED) of BL Lacs is often comprised of two bumps, one peaking at lower (radio to X-ray), the other peaking at higher (above X-ray) energies. In leptonic scenarios, the lower energy component is generated by synchrotron emission of relativistic electrons moving inside the jet. The higher energy component is due to the inverse Compton scattering of the electrons off the photons of the self-generated synchrotron photon field (SSC models, see for instance Marscher & Gear 1985), or off the photons provided externally by other regions of the source (External Compton or EC models, see for instance Dermer & Schlickeiser 1993).

The VHE γ-ray emission in hadronic scenarios can also be explained by the interactions of relativistic protons with ambient photons (Mannheim 1993) or magnetic fields (Aharonian 2000). Depending on the position of the synchrotron component, BL Lacs are subdivided into Low-frequency peaked (LBL) if the maximum of the emission is in the infrared band, and High-frequency peaked (HBL) if the emission is peaked in the UV/X-ray band.

1RXS J101015.9–311909 belongs to the ROSAT All Sky Survey Bright Source Catalog (RASS/BSC) of soft (0.1–2 keV) X-ray sources (Voges et al. 1999), with a flux of \( 2.9 \times 10^{-11} \) erg cm\(^{-2}\) s\(^{-1}\). It is located at a position of \( \alpha = 10^h 5' 14.9'' \), \( \delta = -31^\circ 19' 09'' \) and has a redshift of \( z = 0.14 \) (see Piranomonte et al. 2007, for both measurements). The source is present in the NRAO VLA Sky Survey (NVSS) catalogue of radio sources at 1.4 GHz (Condon et al. 1998), which lists its flux density as 73.5 ± 2.7 mJy. A radio flux of 89.5 ± 3.6 mJy in the 843 MHz band has been measured by the SUMSS radio survey (Bock et al. 2011). Due to its extreme value of the X-ray to radio flux ratio and its high X-ray flux, 1RXS J101015.9–311909 passed the criteria for inclusion in the Sedentary Multi-Frequency Survey catalogue (Giommi et al. 2005). This catalogue specifically selected HBLs and thus presented an obvious choice for the extension of the list of VHE BL Lac candidates. 1RXS J101015.9–311909 also fulfilled the criteria proposed in Costamante & Ghisellini (2002), where BL Lac candidates are considered interesting targets if they exhibit high levels of both X-ray and radio emission.

Following these indications, observations of this source with H.E.S.S. started at the end of 2006, yielding the discovery of γ-ray emission from 1RXS J101015.9–311909 (see Sect. 2) reported here. By combining this information with other multi-wavelength data, the properties of the detected emission and its physical implications are discussed. The HE emission of the source has been studied with Fermi/LAT public data between 100 MeV and 200 GeV and results are reported here in Sect. 3.1. Analysis of data at lower energy bands is carried out to understand the emission from this source: Swift (data from the XRT and UVOT telescopes) are analysed and discussed in Sects. 3.2 and 3.3, and optical data from the xrom (Automatic Telescope for Optical Monitoring, Hauser et al. 2004) telescope located on the H.E.S.S. site and taken mainly contemporaneously to the H.E.S.S. data, are analysed and discussed in Sect. 3.4. Finally, in Sect. 4 all the available data are used to study the global SED of the source in the context of a simple SSC scenario.

### 2. H.E.S.S. observations and results

H.E.S.S. is an array of four imaging Cherenkov telescopes located in the southern hemisphere in the Khomas Highland of Namibia (Aharonian et al. 2006a), that detects cosmic γ-rays in the 100 GeV to 100 TeV energy range. Each of the telescopes is equipped with a segmented mirror of 107 m\(^2\) area and a camera composed of 960 photomultipliers covering a large field-of-view (FoV) of 5° diameter. The stereoscopic system works in a coincidence mode, requiring at least two of the four telescopes to trigger the detection of an extended air shower. The trigger threshold, defined as the peak of the differential γ-ray rate for a Crab-like source at Zenith (Funk et al. 2004), is about 100 GeV and increases with increasing zenith angle.

Observations of 1RXS J101015.9–311909 were carried out with H.E.S.S. in a campaign of 64 h of observation time between 2006 and 2010. These cover a range of zenith angles between 8° and 28°, giving an average zenith angle of 12.9°, with a pointing offset of 0.5° relative to the nominal position of the source (see Table 1 for all details). The data from a total high-quality live-time of \~48.7 h (after hardware and weather quality selection criteria were applied with a procedure similar to that described in Aharonian et al. 2006a) have been analysed to search for emission at the nominal position of the source.

The analysis of the \( \geq 100 \) GeV γ-ray emission from this AGN is carried out with the analysis procedure described in Becherini et al. (2011), where an enhanced low-energy sensitivity with respect to standard analysis methods (Aharonian et al. 2006a) is achieved. This new analysis method is based on a multivariate signal-to-background discrimination procedure using both previously-known and newly-derived discriminant variables which depend on the physical shower properties, as well as its multiple images. In order to have a lower threshold for this source, the analysis configuration with a charge value

Notes. The columns represent the year in which the source has been observed, the start and end date of observations in MJD, the number of good-quality runs available \( N_{\mathrm{ons}} \), the corresponding exposure time in hours (LT), the mean observation zenith angle Zen in degrees, the number of ON- \( (N_{\mathrm{ON}}) \) and OFF-source \( (N_{\mathrm{OFF}}) \) events, the number of excess events \( N_{\gamma} \) and the significance of the detection in units of standard deviations \( \sigma \). The observation offset and the background normalization factor \( \alpha \) (see text) for all datasets presented in the table are 0.5° and 0.09, respectively.

\(^{1}\) This is the position from the RASS/BSC.
of 40 photoelectrons has been used as a minimal required total amplitude for the cleaned and parametrized image in each telescope.

The VHE γ-ray emission from the BL Lac object 1RXS J101015.9−311909 is detected using the reflected background modelling method (Aharonian et al. 2006a) with a statistical significance of 7.1 standard deviations. The significance from a point-like source is 3.1, corresponding to an excess of 263 counts at the nominal position of the source, the total number of ON- and OFF-source events being $N_{\text{ON}} = 1416$ and $N_{\text{OFF}} = 12686$, respectively, with a background normalization factor $\alpha = 0.09$.

The VHE γ-ray excess image obtained with the Ring background modelling method (Aharonian et al. 2006a) is shown in Fig. 1, while Fig. 2 shows the ON-source and normalized OFF-source angular distributions (θ̂) for all H.E.S.S. observations: the background is rather flat, as expected at very small θ̂, and there is a clear excess at small values of θ̂, corresponding to the observed signal. A fit to the excess events of a point-like source model convolved with the H.E.S.S. point-spread function (PSF) yields a position $\alpha_{2000} = 10^{5}\pm15.03^\circ \pm 3.77^{\text{stat}} \pm 1.56^{\text{sys}}$ and $\delta_{2000} = -31^\circ 18' 18.4'' \pm 41.6^{\text{stat}} \pm 20.9^{\text{sys}}$, consistent with the position of the radio and X-ray source (see Fig. 3). The 3σ upper limit to the intrinsic source extension calculated at the best fit position is 3.4''.

The time-averaged differential VHE γ-ray spectrum of the source, derived using the forward-folding technique described in Piron et al. (2001), is presented in Fig. 4. The spectrum is well fitted by a power-law function $dN/dE = \phi_0 \times \left(E/1\text{ TeV}\right)^{-\Gamma}$ with a normalization of $\phi_0 = (1.87 \pm 0.66^{\text{stat}} \pm 0.37^{\text{sys}}) \times 10^{13} \text{ cm}^{-2} \text{s}^{-1} \text{TeV}^{-1}$ and photon index $\Gamma = 3.08 \pm 0.42^{\text{stat}} \pm 0.20^{\text{sys}}$. The differential flux at the decorrelation energy ($E_{\text{dec}} = 0.51\text{ TeV}$) is $\phi_{E_{\text{dec}}} = (1.47 \pm 0.31^{\text{stat}} \pm 0.29^{\text{sys}}) \times 10^{-12} \text{ cm}^{-2} \text{s}^{-1} \text{TeV}^{-1}$. The integral flux above the analysis threshold $E_{\text{th}} = 0.2 \text{ TeV}$ is $\phi(E > E_{\text{th}}) = (2.35 \pm 0.64^{\text{stat}} \pm 0.47^{\text{sys}}) \times 10^{-12} \text{ cm}^{-2} \text{s}^{-1} \text{TeV}^{-1}$, corresponding to ~0.8% of the flux of the Crab nebula above the same threshold. No significant variability is detected; the integral flux is seen to be constant within errors over the H.E.S.S. dataset, as shown in Fig. 5. A fit of the period-by-period light curve with a constant value yields a $\chi^2/\text{d.o.f.} = 11.39/9$, with a probability of 25%. The measured normalized excess variance of 0.44 ± 0.71 on the same light curve yields a 99% confidence level upper limit on the fractional variance of ≤151%, as calculated using the method of Feldman & Cousins (1998). No variability can be seen either in other time binnings tested (year-by-year or run-by-run). All analysis results have been cross-checked and confirmed with an independent method (de Naurois & Rolland 2009), which gives consistent results.

3. Multi-wavelength observations

3.1. Analysis of Fermi/LAT data

1RXS J101015.9−311909 has been associated with the object 2FGL J1009.7−3123 in the Fermi/LAT second source catalogue (Abdo et al. 2011). A Fermi/LAT data analysis is performed on the publicly available data, spanning the time interval from 2008-08-04 (MJD 54 682) to 2011-01-01 (MJD 55 562), using the binned likelihood method (Atwood et al. 2009) from the Science Tools package V. v9r23p1, following the procedure recommended by the Fermi/LAT collaboration.

The isotropic model iso_p7v6source is used to account for both the extragalactic diffuse emission and residual instrumental effects.

2 Calculated following Eq. (17) of Li & Ma (1983).

3 In the reflected background method α is just the reciprocal of the number of OFF-source regions considered.

4 For this analysis the threshold energy is defined as the energy at which the effective detection surface exceeds two hectares and where the energy bias is less than twice the energy resolution.

5 A H.E.S.S. observing period is the period between two full moons.

6 See Vaughan et al. (2003) for definitions of normalized and fractional excess variance.

7 See http://fermi.gsfc.nasa.gov/ssc/data/analysis
The corresponding photon index is \( \Gamma = 2.97 \pm 0.15 \) and the highest energy photon from the direction of the source (i.e., within the 95% containment radius of the PSF at the given energy) has an energy of 276 GeV. Other, more complex spectral shapes like a log-parabola or a broken power-law do not result in a significant improvement of the fit, and thus the power-law spectral shape is used in the remainder of this paper. The resulting spectral slope under these assumptions is consistent with the value found in the 2FGL catalogue, which gives \( \Gamma = 2.24 \pm 0.14 \) _stat_

However, there is evidence for a dependence of the photon index on the chosen energy threshold in the data analysis as summarized in Table 2. The spectrum of the source tends to harden with an increasing low-energy cut, which could be an indication of a curved spectrum. Future observations with Fermi/LAT may enable a significant detection of a possible curvature of the spectrum compared to a pure power-law.

To further check these results, a test was performed by modelling the Galactic diffuse emission with a power-law spectrum, instead of using a constant flux normalisation for this component, as is usually recommended by the Fermi/LAT team. Such an energy-dependent spectrum for this component would be an indication for a mis-modelled Galactic diffuse emission in the analysis, and could affect the hardening tendency as a function of the energy threshold reported in Table 2. When using a threshold of 100 MeV, the latter test results in a photon index of \( \Gamma = 0.07 \pm 0.01 \) for the Galactic diffuse component, while the spectral results for the AGN remain fully compatible with those reported in Table 2. This slight energy-dependence of the spectrum of the Galactic model just reflects the fact that the mechanism responsible for the HE emission from the Galaxy is not yet perfectly understood, but does not strongly affect our results. While at each of the energy thresholds the count map of the RoI exhibits a visible gradient due to the Galactic diffuse emission, no such gradient is present in the residual map after subtraction of the Galactic and extragalactic models and the 2FGL sources (including 1RXS J101015.9–311909), being rather flat within the counting error. This shows that the normalisation of the Galactic diffuse emission is under control and well-modelled in this analysis.

In the following, we will adopt the results of Fermi/LAT data analysis using the two energy thresholds of 300 MeV and 1 GeV, see Fig. 4. The choice of a 300 MeV threshold is made in order to minimise a possible contamination at low energies from neighbouring sources and from the Galactic diffuse emission. This choice takes into account the tendency of the spectrum to harden with increasing energy threshold, while not losing too many source photons due to this cut. We choose 1 GeV as a second threshold in order to study how the evaluation of the Fermi/LAT slope affects the modelling of the overall SED (see Fig. 7).

The Fermi/LAT binned spectral points shown in Fig. 7 are computed by running gtlike in five contiguous energy bins, using the model parameters from the likelihood fit on the energy range 1 GeV–200 GeV, where the spectral index of 1RXS J101015.9–311909 was fixed to the best value of \( \Gamma = 1.71 \) (see Table 2). An upper limit on the flux in a given energy bin was computed if TS < 9. The resulting fluxes for all analyses can be found in Table 2.

The Fermi/LAT light curves, for the two chosen threshold energies, are shown in Fig. 5, where the data are presented in a 6-month binning: given the low photon statistics, no significant variability is found in the 25 months of data. This was checked using other time binnings ranging from 90 to 180 days.

The Fermi/LAT position of 1RXS J101015.9–311909 has been optimized using the tool gtfindsrc, and the best fit was found to be at the position \((a_{\text{J2000}}, \delta_{\text{J2000}}) = (10^{h}09^{m}49^{s}.51, -31^\circ24'21.9'')\) which is fully consistent with the position reported in the 2FGL catalogue (~3′ away). The 1σ contour
bow-ties represent the E_300 MeV and E_1 GeV thresholds in a 6-month binning. The Fermi/LAT systematic uncertainty on the spectral index is 10% at 100 MeV, decreasing to 5% at 560 MeV and increasing to 10% at 10 GeV and above, see Abdo et al. (2011).

presented in Fig. 3 was derived from the TS map computed on the Rol, using the best-fit position of the source.

Notes. The columns correspond to the energy threshold in MeV, E_{th}, the photon index, \Gamma, the test statistic (TS), the integral flux above threshold \phi(E > E_{th}) in units of 10^{-8} \text{ph cm}^{-2} \text{s}^{-1} and the decoloration energy (E_{dec}) in MeV. The Fermi/LAT systematic uncertainty on the spectral index is 10% at 100 MeV, decreasing to 5% at 560 MeV and increasing to 10% at 10 GeV and above, see Abdo et al. (2011).

3.2. Swift/XRT

The X-ray Telescope (XRT) (Burrows et al. 2005) on board the γ-ray burst mission Swift (Gehrels et al. 2004) observed 1RXS J101015.9−311909 three times during 2007-05-17 and 2007-05-18 (see Table 3 for the total exposure time available with Swift/XRT). The first and third observations were performed in photon-counting (pc) mode, while the second observation was performed in windowed-timing (wt) mode. Cleaned event files have been reduced using HEASoft\(^8\), V. 6. 7. Source spectra and lightcurves have been extracted using XSelect, V. 2. 4a, and the spectral fitting has been performed using XSpec, V. 12. 5. 1. Response matrices and ancillary response files have been provided by the Swift/XRT instrument team. The source count-rate is equal to 0.4 counts s\(^{-1}\) for the three observations. The presence of a pile-up effect in the data has been checked following the prescriptions of the Swift/XRT instrument team\(^9\), leading to the conclusion that it does not affect the observations.

\(^8\) http://heasarc.nasa.gov
\(^9\) http://www.swift.ac.uk/pileupthread.shtml
As no significant variability has been observed, the two spectra obtained in the pc-mode have been summed using matlpha, V. 4.1.0, and fitted together with the second observation spectrum. Data below 0.3 keV have not been included in the analysis\(^{10}\) while the last significant bin is at \(\approx 7\) keV. The spectra have been rebinned using grppha, V. 3.0.1, in order to have a minimum of 10 counts per bin. The Galactic column density \(N_H\) has been fixed at 7.79 \(\times 10^{20}\) cm\(^{-2}\), as evaluated by Dickey \& Lockman (1990).

A fit performed using a simple power-law function with Galactic absorption gives \(\Gamma = 2.15 \pm 0.06\) and normalization factor \(C_{1\,\text{keV}} = (3.0 \pm 0.1) \times 10^{-3}\) keV\(^{-1}\) cm\(^{-2}\) s\(^{-1}\) (F-test probability equal to \(4 \times 10^{-5}\)) if a broken power-law is assumed, as shown in Table 4, case A, where the best fit parameters for the two photon indices, break energy and normalization are presented. The absorbed flux in the 0.3–7 keV energy band is found to be \((1.04^{+0.04}_{-0.03}) \times 10^{-11}\) erg cm\(^{-2}\) s\(^{-1}\).

The break observed in the X-ray spectrum (see Fig. 6) can either be intrinsic or external, i.e. due to an additional absorption component in the AGN host galaxy. For an extensive discussion about this topic see Perlman et al. (2005), where based on the analysis of XMM-Newton spectra of 13 different BL Lac objects, a discussion of the intrinsic or external origin of the observed spectral curvature is given, concluding that the first hypothesis would be preferred. The hypothesis of an external origin of the break has been tested by fitting the Swift/XRT data with a power-law emission function including absorption by Galactic material (fixed at the value given by Dickey \& Lockman 1990) plus a second absorber located at the redshift of the host galaxy with adjustable column density. The best fit in this case (case B in Table 4) is statistically equivalent to the broken power-law, the evaluation of the second absorber column density being \(N_{H,\text{free}} = 9.9 \times 10^{20}\) cm\(^{-2}\). This second absorber is, however, poorly constrained compared to the Galactic one.

It should be noted that, given the relatively low redshift of the source, the location of the absorber cannot be constrained. In particular, the same absorption effect could be obtained by multiplying by a factor of \(\sim 2\) the contribution of the Galactic absorption in the direction of the source. However, such a high value of the Galactic column density is not consistent with the range of \(N_H\) measured in a circle of 1° around the nominal position of the source (Dickey \& Lockman 1990).

The deabsorbed X-ray spectra of the source assuming either an intrinsic break of the spectrum (corrected only for Galactic absorption), or an external one (corrected for both absorbers), are shown in Fig. 6.

Notes. In the photon-counting (pc) mode the entire charge-coupled device is read out, while in the windowed-timing (wt) mode only the central rows of the camera are read, increasing the time resolution of the instrument.

As no significant variability has been observed, the two spectra obtained in the pc-mode have been summed using matlpha, V. 4.1.0, and fitted together with the second observation spectrum. Data below 0.3 keV have not been included in the analysis\(^{10}\) while the last significant bin is at \(\approx 7\) keV. The spectra have been rebinned using grppha, V. 3.0.1, in order to have a minimum of 10 counts per bin. The Galactic column density \(N_H\) has been fixed at 7.79 \(\times 10^{20}\) cm\(^{-2}\), as evaluated by Dickey \& Lockman (1990).

A fit performed using a simple power-law function with Galactic absorption gives \(\Gamma = 2.15 \pm 0.06\) and normalization factor \(C_{1\,\text{keV}} = (3.0 \pm 0.1) \times 10^{-3}\) keV\(^{-1}\) cm\(^{-2}\) s\(^{-1}\) (F-test probability equal to \(4 \times 10^{-5}\)) if a broken power-law is assumed, as shown in Table 4, case A, where the best fit parameters for the two photon indices, break energy and normalization are presented. The absorbed flux in the 0.3–7 keV energy band is found to be \((1.04^{+0.04}_{-0.03}) \times 10^{-11}\) erg cm\(^{-2}\) s\(^{-1}\).

The break observed in the X-ray spectrum (see Fig. 6) can either be intrinsic or external, i.e. due to an additional absorption component in the AGN host galaxy. For an extensive discussion about this topic see Perlman et al. (2005), where based on the analysis of XMM-Newton spectra of 13 different BL Lac objects, a discussion of the intrinsic or external origin of the observed spectral curvature is given, concluding that the first hypothesis would be preferred. The hypothesis of an external origin of the break has been tested by fitting the Swift/XRT data with a power-law emission function including absorption by Galactic material (fixed at the value given by Dickey \& Lockman 1990) plus a second absorber located at the redshift of the host galaxy with adjustable column density. The best fit in this case (case B in Table 4) is statistically equivalent to the broken power-law, the evaluation of the second absorber column density being \(N_{H,\text{free}} = 9.9 \times 10^{20}\) cm\(^{-2}\). This second absorber is, however, poorly constrained compared to the Galactic one.

It should be noted that, given the relatively low redshift of the source, the location of the absorber cannot be constrained. In particular, the same absorption effect could be obtained by multiplying by a factor of \(\sim 2\) the contribution of the Galactic absorption in the direction of the source. However, such a high value of the Galactic column density is not consistent with the range of \(N_H\) measured in a circle of 1° around the nominal position of the source (Dickey \& Lockman 1990).

The deabsorbed X-ray spectra of the source assuming either an intrinsic break of the spectrum (corrected only for Galactic absorption), or an external one (corrected for both absorbers), are shown in Fig. 6.

3.3. Swift/UVOT

The Swift satellite carries an Ultra-Violet/Optical Telescope (UVOT) (Roming et al. 2005), which observed 1RXS J101015.9–311909 simultaneously with XRT. Six different filters are available: V and B in optical and U, UVW1, UVM2 and UVW2, in the ultra-violet, in order of increasing frequency. Counts have been extracted in a 5′ radius of aperture, and magnitudes and fluxes have been evaluated using uvotmaghist, V. 1.1. The correction for Galactic extinction has been done following Roming et al. (2009), assuming \(E_{B-V} = 0.104\) and 0.224 for case A and B respectively, where \(E_{B-V}\) is the difference of the total extinction in the B and V filters. The evaluation of \(E_{B-V}\) has been done using \(N_H = 7.79\) and \(16.79 \times 10^{20}\) cm\(^{-2}\), for case A and B, respectively, and \(N_{H,\text{free}}/E_{B-V} = 7.5 \times 10^{21}\) cm\(^{-2}\), as given in Jenkins \& Savage (1974). No significant variability in the data is observed. Therefore, the mean flux values measured by UVOT for each filter are used for the study of the SED (see Sect. 4).

3.4. ATOM

ATOM (Hauser et al. 2004) is a 75-cm optical telescope located at the H.E.S.S. site. 1RXS J101015.9–311909 has been regularly observed with ATOM from January 2008 to June 2011. On
have been determined using a 4′′ (as defined by Bessell 1990) while the rest of the observations radio survey (see Sect. 1).

The measured variability time-scale is roughly 1 day, corresponding to the minimum time between two detections.

The lowest measured variability time-scale is roughly 1 day, corresponding to the minimum time between two detections.

The measured normalized excess variances of (0.014 ± 0.005) and (0.011 ± 0.002) confirm that there is a significant variability in both the blue and red bands, respectively. The lowest detected variability time-scale is roughly 1 day, corresponding to the minimum time between two observations. The measured J band spectral flux density, not shown in Fig. 5, is (7.84 ± 0.33) × 10^{-16} erg cm^{-2} s^{-1} Å^{-1}. For the SED (Sect. 4), the mean flux obtained from the data measured corrected for Galactic extinction (again using $E_{B-V} = 0.104$ and 0.224 for case A and B, respectively), is considered; the error bars show the flux variability range observed.

4. SSC modelling of the SED

The non-simultaneous SED of 1RXS J101015.9−311909, corrected for Galactic absorption, is shown in Fig. 7. Historical data taken from NED[1] are also shown. Before 2006 the source has been observed in radio, infrared, optical and X-rays. A discussion of the accuracy of the cross-calibration between Fermi/LAT and H.E.S.S. (evaluated at 4% based on the Crab nebula) can be found in Meyer et al. (2010).

The optical flux contribution from the host galaxy has been evaluated using data from the 2MASS Extended Source catalogue (Jarrett et al. 2000). Based on the magnitude values evaluated for different radii of aperture ($r > 5′′$) and the effective radius of the galaxy ($r_{eff} = 3.03′′$ in the J band), we estimate this contribution in a 4′′ radius of aperture as $m_{gali} = 14.3$ for the magnitude in the J band, following Young (1976). The magnitude obtained has been used to properly rescale the template of a giant elliptical galaxy spectrum (evaluated using PEGASE) (Fioc & Rocca-Volmerange 1997).

As shown in Fig. 7, in infrared light, the host galaxy dominates the AGN emission. This is consistent with the optical spectrum measured by Piranomonte et al. (2007) when evaluating the redshift of the source (see Figs. 2 and A.1 in their paper) and with the fact that the variability amplitude in the B band is significantly larger than that in the R band.

The emission from the active nucleus is described using a stationary one-zone SSC code (Katarzyński et al. 2001): a spherical plasma blob (characterised by its radius $R$) moving with Doppler factor $δ$ in the relativistic jet (with $θ$ being the angle to the line of sight) is filled with a homogeneous magnetic field $B$ and a stationary, non-thermal electron distribution. The synchrotron emission from these electrons is responsible for the low energy bump, peaking in the X-ray band, and is then Compton-upscattered by the electrons themselves, to produce the γ-ray emission. Pair production ($γ + γ → e^+ + e^-$) inside the blob is not negligible, and is taken into account using the cross section

Table 5. Parameters used for the SSC modelling of the SED of 1RXS J101015.9−311909 and derived physical quantities.

Notes. Summary of the SED parameters for the two Fermi/LAT spectra considered (low-energy threshold equal to 300 MeV and 1 GeV) and for the two cases proposed in the Swift/XRT analysis (case A and case B). For all the cases considered, the minimum and maximum Lorentz factors of the electron distribution are set to \( \gamma_{e,\text{min}} = 300 \) and \( \gamma_{e,\text{max}} = 5 \times 10^6 \) respectively: the angle to the line of sight is \( \theta = 1^\circ \), the Doppler factor is \( \delta = 30 \), and the index of the electron distribution after the break is \( \alpha_2 = 4.0 \). The electron-distribution normalization parameter \( K \) is in units of cm\(^{-3}\); the magnetic field \( B \) is in G; the emitting-region size \( R \) is in cm; the energy densities \( u_e, u_B \) are in erg cm\(^{-3}\); the variability timescale \( \tau_{\text{var}} \) is in hours and the jet luminosity \( L_{\text{jet}} \) is in ergs s\(^{-1}\).

The two previously-mentioned X-ray spectral hypotheses (assuming an intrinsic break or an additional absorption) have been considered as lower and upper limits for the synchrotron emission from the blob. In case A, the synchrotron peak energy corresponds to the observed X-ray break energy, while in case B, the synchrotron peak falls between UV and X-rays. Whereas in case A the emission from the blob cannot explain both the X-ray and optical/UV data, in case B the synchrotron component, together with the emission from the host galaxy, can reproduce the infrared to X-ray observations. In both cases, the historical radio data are not taken into account, as it is more likely that they are produced in the extended jet. In order to study how the evaluation of the Fermi/LAT (which depends on the low-energy threshold, as described in Sect. 3.1) affects the overall SED, the modelling has been performed for the two Fermi/LAT spectra evaluated above 300 MeV and 1 GeV. For simplicity, only the modelling of the SED with the Fermi/LAT spectrum evaluated above 1 GeV is presented in Fig. 7.

The minimum and maximum Lorentz factors of the electron distribution cannot be constrained by the data, and they have been fixed at \( \gamma_{e,\text{min}} = 300 \) and \( \gamma_{e,\text{max}} = 5 \times 10^6 \). The index of the electron distribution after the break \( \alpha_2 \) is completely constrained by the observed X-ray photon index above the break, and has been fixed at 4.0. The slope \( \alpha_1 \) is constrained by the Fermi/LAT photon index (for the two cases, A and B) and by the optical/UV data points (only for case B), and it has been fixed at 2.2 and 2.0 for a Fermi/LAT spectrum evaluated above 300 MeV and 1 GeV, respectively.

A good description of the SED can be obtained assuming an angle to the line of sight \( \theta = 1^\circ \) and a Doppler factor \( \delta = 30 \), corresponding to a bulk Lorentz factor of 16. The other free parameters (\( B, R, \gamma_{e,\text{break}}, K \)) are different between the cases considered, and their values are indicated in Table 5, together with the evaluation of the electron energy density \( u_e = mc^2 \int d\gamma \gamma N(\gamma_e) \) and the magnetic energy density in the blob \( u_B = B^2 / 8\pi \). The \( u_e / u_B \) value is higher in case A (intrinsic break, and higher synchrotron peak energy) than in case B (additional absorption effect, and lower synchrotron peak energy), reflecting the fact that the ratio between the inverse Compton and the synchrotron component is higher in the first case. The lower limit on the variability timescale evaluated for the emitting region size and the Doppler factor assumed in the modelling, roughly corresponds to 1 and 25 h for the cases A and B, respectively, consistent with the variability time-scale observed by ATOM.

The difference between the Fermi/LAT spectra evaluated for different energy thresholds affects the evaluation of the electron-distribution slope before the break (\( \alpha_1 \)), and, consequently, it induces a variation on the normalization factor \( K \) and on the break Lorentz factor \( \gamma_{e,\text{break}} \), modifying the value of the electron energy density inside the emitting region.

In case A, the observed flux at low frequency (infrared to UV) cannot be explained by the blanb. An additional component is required (not shown in Fig. 7), such as the emission from the extended jet, dominating the non-thermal continuum from radio to UV, and being responsible for the variability observed in ATOM data.

On the other hand, in case B, the low-frequency emission can be described by the blob-in-jet component plus the contribution from the host galaxy, with the former being at the origin of the observed optical variability.

It should be noted that, in this case, the UV flux is slightly underestimated. To better describe the data, the model would need a harder slope \( \alpha_1 \) in apparent conflict with the GeV constraints derived from Fermi/LAT. However, the uncertainties (both statistical and systematic) on the evaluation of the GeV slope, as well as on the value of the second absorber in case B (the error on the \( E_{B,V} \) value used for the dereddening of the data is about 20%; this uncertainty has not been taken into account in the plotting of the SED), can still explain this discrepancy.

As mentioned above, the two cases discussed here (A and B) are best considered as lower and upper limits for the SSC blazar emission. The real scenario may be more complex and lie between these two limiting cases.

5. Conclusions

The blazar 1RXS J101015.9−311909 has been observed by H.E.S.S. between 2006 and 2010, leading to the discovery of its VHE emission with a significance of 7.1 standard deviations. The time-averaged VHE spectrum of this blazar is soft, with a photon index of \( \Gamma = 3.08 \pm 0.42_{\text{stat}} \pm 0.20_{\text{sys}} \) and a flux 0.8% of that of the Crab nebula. The detection has been made using more powerful analysis methods, which provide an enhanced sensitivity at lower energies. Observations at other wavelengths have
been analysed in order to have a multi-band view of the SED of this AGN newly-detected in the VHE range. In particular, a careful analysis of the HE emission in Fermi/LAT data reveals a detection of this AGN at a significance level of about 8.2 standard deviations.

No detectable variability is seen in the available VHE (HESS.), HE (Fermi/LAT) or X-ray (Swift/XRT) datasets, thus containing the origin of the observed X-ray break. The SED can be reproduced reasonably well using a stationary one-zone SSC model, with parameter values compatible with those commonly assumed for relativistic jets. However, if the origin of the X-ray break is intrinsic, the model requires another component (most likely the blazar emission at that wavelength). The SED can be reproduced in order to determine whether optical and UV data.

Current uncertainties on the intrinsic X-ray spectrum, together with the non-simultaneity of the infrared to UV data, remain limiting factors for a realistic modelling of the low-energy bump. Future simultaneous multi-wavelength observations are required in order to determine whether optical/UV and X-ray photons are produced in the same emitting region, thus constraining the origin of the observed X-ray break.

The high-energy part of the SED turns out to be better constrained with modelling only limited by the current uncertainty in the Fermi/LAT spectral index. Given the surveying strategy of Fermi/LAT, further data are expected to allow a more precise modelling of the source to be attained.

Acknowledgements. The support of the Namibian authorities and of the University of Namibia in facilitating the construction and operation of HESS is gratefully acknowledged, as is the support by the German Ministry for Education and Research (BMBF), the Max Planck Society, the French Ministry for Science and Technology, the South African Department of Science and Technology and the National Research Foundation, and the University of Namibia. We appreciate the excellent work of the technical support staff in Berlin, Durham, Hamburg, Heidelberg, Palaiseau, Paris, Saclay, and in Namibia in the construction and operation of the equipment. This research has made use of the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. We acknowledge the use of public data from the Swift data archive. This research has made use of data and software provided by the Fermi Science Support Center, managed by the HEASARC at the Goddard Space Flight Center. This publication makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation.
